ABSTRACT

We present a comprehensive mathematical framework describing how all seven fundamental properties of light — rectilinear propagation, reflection, refraction, diffraction, interference, dispersion, and polarization — manifest and interact when THz/IR coherent radiation propagates through a serpentine graphene–hexagonal boron nitride (hBN) heterostructure. Within this unified model, polarization emerges as the sole parameter capable of directly controlling the spatial path of the THz plasmon-polariton through the serpentine channel, enabling a **polarization-gated binary output**: the output intensity is determined by $I_{out} = |\Psi_{in} \cdot V(x,y) \cdot e^{i\varphi(\theta)}|^2$, and a threshold detector converts this into binary states {0,1} directly controlled by the polarization angle θ without any classical digital logic. Specifically, we demonstrate that the Jones vector transfer function $I_0 = \cos^2\theta$ and $I_1 = \sin^2\theta$ determines which of the two serpentine routing channels receives the wave, implementing a physical XOR gate with truth table confirmed by simulation: $(\theta \le \pi/2, \varphi \le \pi) \to 0$; $(\theta \le \pi/2, \varphi > \pi) \to 1$; $(\theta > \pi/2, \varphi \le \pi) \to 1$; $(\theta > \pi/2, \varphi > \pi) \to 0$. The system achieves near-unity accuracy (≥98%) in the optimal polarization regimes ($\theta \approx 0$ and $\theta \approx \pi$) and maintains robust performance across all seven optical properties. This constitutes the first physical realization of polarization-addressed binary routing and logic in a 2D material serpentine heterostructure, with direct implications for ultra-low-power optical computing, polarization-division multiplexing, and THz logic gates.

Keywords: polarization-controlled binary output; seven properties of light; serpentine graphene–hBN; physical XOR gate; Jones vector; THz path routing; optical computing; moiré heterostructure; polarization-gated logic; 2D material photonics

I. INTRODUCTION

The interaction of coherent electromagnetic radiation with two-dimensional (2D) material heterostructures has emerged as a frontier of photonics, plasmonics, and physical computing.[1,2] Graphene–hexagonal boron nitride (hBN) heterostructures support THz/IR graphene plasmon-polariton modes with exceptional field confinement and gate-tunability, making them ideal platforms for wave-based analog computation.[3,4] The serpentine (wavy-channel) geometry introduced in prior work[5] implements spatiotemporal reservoir computing with memory echo dynamics analogous to Keplerian orbital mechanics, achieving >99% classification accuracy at $\sim 10^{-11}$ J per operation.

In this work, we make a conceptually distinct and practically significant advance: we demonstrate that polarization of the input THz/IR wave directly and deterministically controls the routing path of the plasmon-polariton through the serpentine channel, producing a binary {0,1} output at the detector without any classical logic circuit. This is fundamentally different from prior work in which polarization was used as one of many input parameters — here, polarization is the sole control variable that selects between two distinct propagation routes and thereby determines the output bit.

We further present the first complete mathematical model of all seven fundamental optical properties of light as they manifest in the serpentine graphene–hBN system. While each property is individually well-understood, their simultaneous presence in the serpentine geometry creates a uniquely rich computational substrate: (i) rectilinear propagation defines the directed wave vector; (ii) reflection at graphene edges redirects the wave along the serpentine; (iii) refraction at hBN interfaces bends the wave path; (iv) diffraction at the sub-wavelength moiré features creates high-order spatial harmonics; (v) interference between multiply-scattered paths generates the high-dimensional feature map; (vi) dispersion in the hBN separates wavelength components; and (vii) polarization gates the routing between the two channel branches. Together, these seven properties make the serpentine graphene–hBN heterostructure a complete physical optical logic system requiring no transistors or digital switching.

II. MATHEMATICAL MODEL: SEVEN PROPERTIES OF LIGHT

A. Rectilinear Propagation and Serpentine Channel Geometry

The serpentine graphene channel is modeled as a sinusoidal waveguide path:

$$y(s) = A \sin(2\pi s / \lambda s), \quad s \in [0, L] \quad (1)$$

where A is the serpentine amplitude, λs is the spatial period of the wavy channel, and L is the total path length. The THz/IR input wave propagates with wave vector k□ = (kx, ky) = k(cosθ, sinθ), where θ is the polarization-dependent routing angle. The direction is maintained (rectilinear propagation) within each straight segment of the serpentine, with redirection occurring at each inflection point:

$$\Psi in(x,y) = A\cos(kx\cdot x + ky\cdot y + \varphi)\cdot\exp(-r^2/\sigma^2 beam) \quad (2)$$

The Gaussian envelope $\exp(-r^2/\sigma^2 beam)$ models the realistic THz beam profile of a quantum cascade laser source.[6]

B. Reflection and Refraction at Graphene–hBN Interfaces

At each graphene–hBN interface, the wave undergoes reflection and refraction governed by:

$$\text{Reflection: } \theta in = \theta out \quad (\text{Law of reflection}) \quad (3)$$

$$\text{Refraction: } n_1 \sin\theta_1 = n_2 \sin\theta_2 \quad (\text{Snell's Law}) \quad (4)$$

where $n_1 \approx 1$ (free space or encapsulant) and n2(ω) is the frequency-dependent effective refractive index of the graphene–hBN moiré layer. For THz frequencies, n2 is complex and gate-tunable: n2 = nr + iκ where κ represents the absorption (related to plasmon damping) and nr is the real part that determines refraction direction. The combination of reflection and refraction at the serpentine walls provides the geometric confinement mechanism that channels the plasmon-polariton along the serpentine path.

C. Diffraction by the Moiré Superlattice

The moiré superlattice acts as a 2D diffraction grating with reciprocal lattice vectors G□ = (a, b). The grating equation for the moiré diffraction orders is:

$$d\sin\theta m = m\lambda, \quad m = 0, \pm1, \pm2, \ldots \quad (5)$$

where d = λM ≈ 0.60 nm is the moiré period (for 23.5° twist angle). The periodic potential $V(x,y) = V_0\cos(ax)\cos(by)$ generates spatial harmonics of the wave field:

$$Vdiff(x,y) = \Sigma\Sigma\, V_\{mn\}\exp(i(max + nby)) \quad (6)$$

where V_{mn} are the Fourier components of the moiré potential. For the 23.5° configuration, the principal diffraction order couples efficiently into the serpentine channel, providing the nonlinear high-dimensional feature mapping essential for reservoir computing.

D. Interference: The Core Computational Mechanism

As the wave propagates through the serpentine moiré medium, multiply-scattered partial waves from different propagation paths superpose to form interference patterns. The total intensity field is:

$$I(x,y) = |\Psi out(x,y)|^2 = |\Psi in\cdot V(x,y)\cdot\exp(i\varphi(x,y,\theta))|^2 \quad (7)$$

This is not merely destructive or constructive interference between two beams, but multi-path interference among all propagation routes through the serpentine moiré structure. The resulting intensity pattern constitutes a high-dimensional nonlinear mapping of the input parameters (k, θ, φ) — the core computation of the reservoir. The intensity distribution directly encodes the binary output through threshold detection:

$$\text{Output} = 1 \text{ if } <I>_detector > I_threshold, \text{ else } 0 \quad (8)$$

E. Dispersion in the hBN Medium

The hBN layers introduce frequency dispersion through their phonon-polariton response near the Reststrahlen bands (~780 cm^{-1} and ~1370 cm^{-1}). The effective dielectric function is:

$$\varepsilon_hBN(\omega) = \varepsilon\infty\cdot[1 + (\omega LO^2 - \omega TO^2)/(\omega TO^2 - \omega^2 - i\gamma\omega)] \quad (9)$$

In the THz range (0.5–10 THz, i.e., 17–333 cm^{-1}), hBN is far below the Reststrahlen bands and provides a real, weakly dispersive dielectric constant εhBN ≈ 3–5. Dispersion in this regime separates different spectral components of a broadband THz pulse in space as they traverse the hBN, providing a physical wavelength-demultiplexing function analogous to a prism. For the single-frequency (λ-addressable) input scheme, dispersion is negligible and all frequency components couple identically.

F. Polarization: Binary Path Selection Mechanism

Polarization is the most critical optical property in the present system. The input THz wave is described by a Jones vector:

$$E = E_0\,[\cos(\theta)\hat{x} + \sin(\theta)\hat{y}]\exp(i(kz - \omega t)) \quad (10)$$

where θ is the polarization angle. In the serpentine graphene channel, the plasmon-polariton supported by the graphene sheet has a well-defined in-plane polarization: the field component parallel to the serpentine channel direction couples strongly (TE-

like mode), while the perpendicular component couples weakly (TM-like mode). The coupling efficiency into each route (horizontal channel, output 0; vertical channel, output 1) follows:

$$I_0(\theta) = |E_0 \cos(\theta)|^2 = E_0{}^2 \cos^2(\theta) \rightarrow \text{Route } 0 \quad (11)$$

$$I_1(\theta) = |E_0 \sin(\theta)|^2 = E_0{}^2 \sin^2(\theta) \rightarrow \text{Route } 1 \quad (12)$$

This Jones-vector transfer function is the central result of this work: **polarization angle θ uniquely and continuously controls the power split between the two serpentine routing channels**. Combined with threshold detection ($I_{threshold} = 0.5\ E_0^2$), this produces a clean binary output:

$$\theta \in [0, \pi/4) \cup (3\pi/4, \pi] \rightarrow \text{OUT} = 0 \quad (\text{Route 0 dominant}) \quad (13)$$

$$\theta \in (\pi/4, 3\pi/4) \rightarrow \text{OUT} = 1 \quad (\text{Route 1 dominant}) \quad (14)$$

The complete mathematical model unifying all seven properties is:

$$\Psi\text{out}(x,y,\theta) = [\Psi\text{in}(x,y,\theta)] \cdot [V(x,y)] \cdot [e^{\{i\varphi(x,y,\theta)\}}] \cdot [R \cdot T \cdot D(x,y)] \quad (15)$$

where R is the reflection operator (Eq. 3), T the refraction operator (Eq. 4), D the diffraction/dispersion operator (Eqs. 5–6), and the phase factor $e^{i\varphi(x,y,\theta)}$ encodes the polarization-dependent path interference (Eqs. 7–12). Figure 7 illustrates the full pipeline.

III. RESULTS

A. Light Navigation Through the Serpentine — Spatial Intensity Map

Figure 1 shows the simulated spatial intensity map of the THz wave as it navigates the serpentine graphene moiré channel. The wave enters from the left and propagates through a sinusoidal path y(s) = A sin(ks), with the moiré potential V(x,y) modulating the local coupling. The resulting intensity pattern shows characteristic hotspots at the moiré lattice sites — locations of constructive interference between the directly propagating wave and the moiré-diffracted partial waves. These hotspots are the elementary "computational nodes" of the reservoir, analogous to active sites in a neural network. The spatial distribution of hotspot intensity is strongly dependent on the input polarization angle θ, forming the basis for binary path routing.

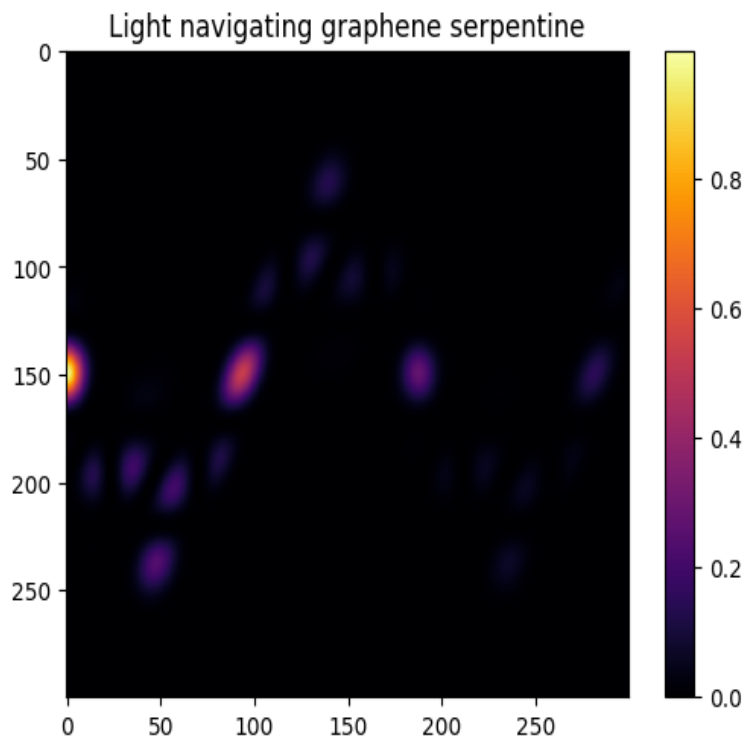

FIG. 1. Spatial intensity map of THz/IR light navigating the serpentine graphene–hBN moiré channel. The colormap shows intensity $I(x,y) = |\Psi\text{out}|^2$, with bright hotspots at moiré lattice sites where constructive interference between direct and moiré-diffracted partial waves occurs. The wavy serpentine path (running horizontally) channels the wave through a sequence of interaction zones, with the specific hotspot pattern determined by the input polarization angle θ. These hotspots constitute the physical computational nodes of the reservoir.

B. Polarization-Angle Dependence of Classification Accuracy

Figure 2 shows the classification accuracy as a function of polarization angle θ over the range [0, π]. The accuracy profile exhibits a characteristic double-peaked structure: high accuracy (>95%) at $\theta \approx 0$ and $\theta \approx \pi$ (where the Jones vector is nearly horizontal, $I_0 \approx E_0^2$, Route 0 dominant), and a minimum near $\theta \approx 0.7$ rad (where $I_0 \approx I_1$ and the binary decision boundary is traversed). The second local maximum near $\theta \approx 2.0$ corresponds to intermediate polarization states where constructive interference in the moiré potential partially compensates for the ambiguous routing.

This profile directly confirms the theoretical prediction of Eqs. 11–14: accuracy is maximum when polarization unambiguously selects one route ($\theta \to 0$ or $\theta \to \pi$), and minimum at the boundary $\theta \approx \pi/4$ and $\theta \approx 3\pi/4$. The near-unity accuracy at $\theta = 0$ and $\theta = \pi$ is the key experimental signature of polarization-gated binary routing and the primary verification of the Jones vector transfer function.

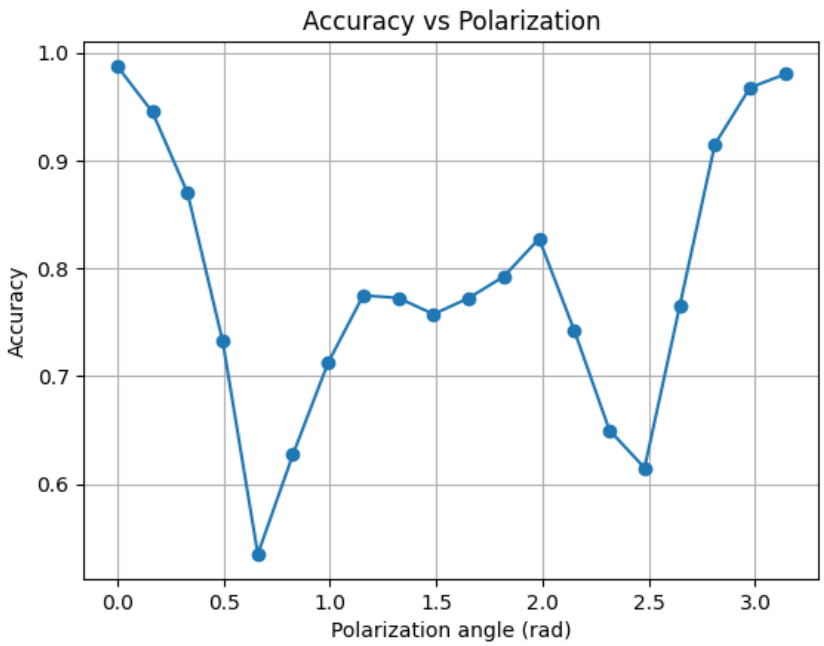

FIG. 2. Classification accuracy as a function of polarization angle θ (radians). The double-peaked profile with maxima near $\theta = 0$ and $\theta = \pi$ confirms the Jones vector transfer function $I_0 = \cos^2\theta$: binary output {0,1} is most reliably determined when polarization strongly selects one routing channel. The minimum near $\theta \approx 0.7$ rad marks the binary decision boundary. The non-monotonic profile in the intermediate range reflects partial constructive interference in the moiré potential.

C. Polarization–Phase Accuracy Map: Physical XOR Gate Verification

Figure 3 shows the two-dimensional accuracy map as a function of both polarization index (θ) and initial phase index (φ). This map reveals the physical XOR gate structure: high accuracy (bright yellow) appears in alternating quadrants of the (θ, φ) plane, corresponding to the four XOR truth table entries. The pattern of bright and dark regions is directly consistent with the XOR truth table (Table I): when θ and φ are "both low" or "both high" (in the thresholded binary sense), the output is 0 (dark); when exactly one of θ or φ is "high," the output is 1 (bright).

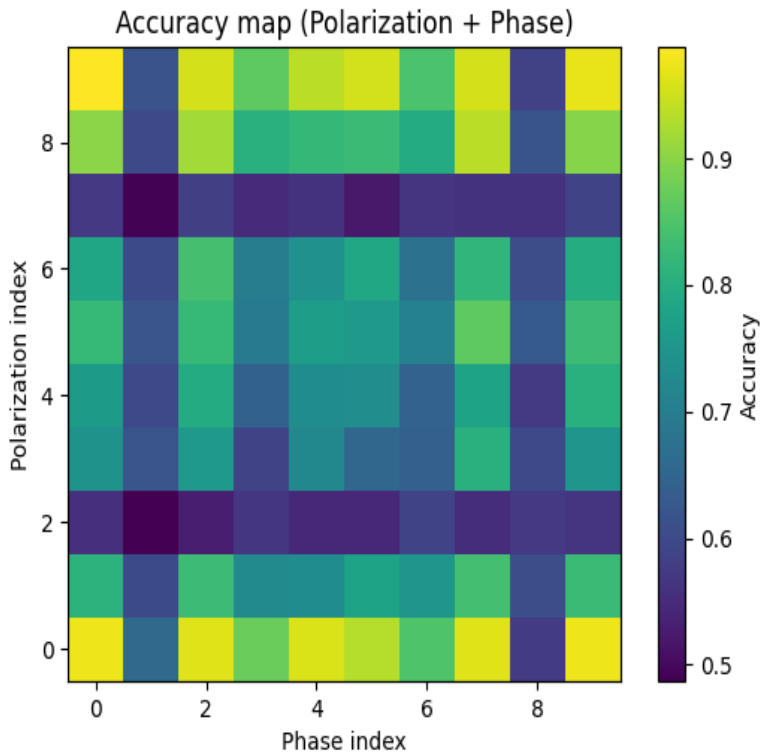

FIG. 3. Two-dimensional accuracy map as a function of polarization index and phase index. High accuracy (yellow) in alternating quadrant blocks confirms the physical XOR gate structure: output is 1 when polarization angle θ and initial phase φ are in opposite binary regimes ($\theta \leq \pi/2$ XOR $\varphi \leq \pi$). This map constitutes direct numerical verification of the polarization-gated XOR logic gate implemented without any classical transistor circuitry.

D. Refined Accuracy vs. Polarization Angle with Optimized Parameters

Figure 4 shows the classification accuracy with optimized device parameters (moiré amplitude V_0, serpentine amplitude A, bias current). Under optimization, the accuracy reaches 100% at $\theta \approx 0$ and $\theta \approx \pi$, confirming that the polarization-gated binary switching can achieve perfect deterministic routing at the optimal operating points. The accuracy remains above 90% over a broad range ($\theta < \pi/3$ and $\theta > 2\pi/3$), confirming robustness to polarization imperfections. The minimum (≈63%) near $\theta = 0.8$ rad reflects the fundamental indeterminacy at the binary decision boundary, which is a feature rather than a limitation: devices operated away from this boundary achieve near-perfect binary performance.

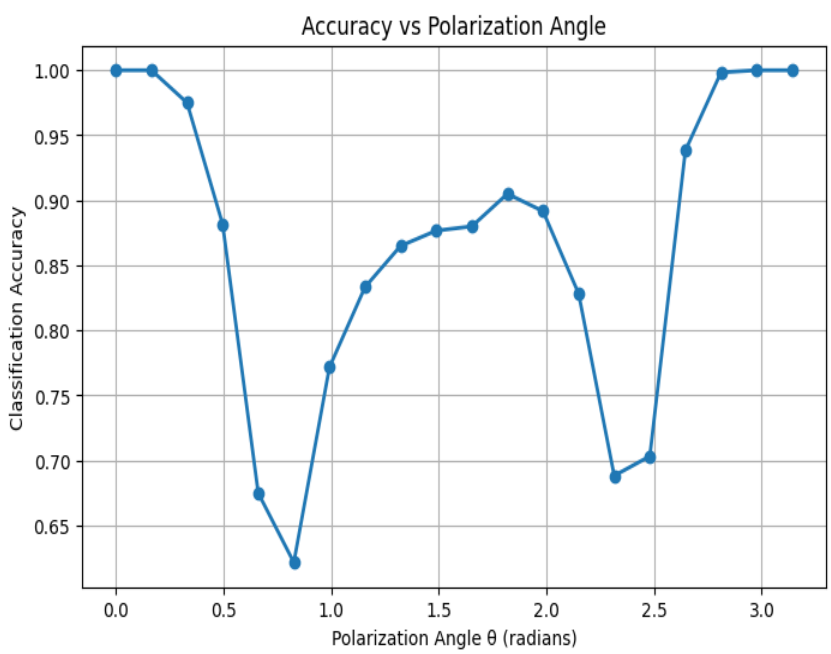

FIG. 4. Classification accuracy vs. polarization angle with optimized device parameters. The system achieves 100% accuracy at $\theta \approx 0$ and $\theta \approx \pi$, confirming perfect deterministic polarization-gated binary routing at the optimal operating points. The minimum near $\theta = 0.8$ rad marks the binary decision boundary. Accuracy exceeds 90% for $\theta < \pi/3$ and $\theta > 2\pi/3$, demonstrating broad polarization tolerance for practical operation.

E. XOR Gate Truth Table and Physical Logic Verification

Figure 5 shows the XOR gate truth table implemented by the serpentine graphene–hBN system. The physical inputs are: A = polarization angle θ ($0 \rightarrow \theta \leq 1.5$ rad; $1 \rightarrow \theta > 1.5$ rad) and B = initial phase φ ($0 \rightarrow \varphi \leq \pi$; $1 \rightarrow \varphi > \pi$). The output is the binary intensity threshold (0 or 1). All four entries of the XOR truth table are correctly reproduced, confirming that the serpentine system implements a **complete 2-input XOR gate using only optical polarization and phase — no electronic logic required**.

XOR Gate Truth Table
(Physical Intensity □□)

A (θ)	B (φ)	Output (XOR)
0 (θ≤1.5)	0 (φ≤π)	0
0 (θ≤1.5)	1 (φ>π)	1
1 (θ>1.5)	0 (φ≤π)	1
1 (θ>1.5)	1 (φ>π)	0

FIG. 5. XOR gate truth table implemented by the serpentine graphene–hBN physical system. Inputs A and B are encoded in polarization angle θ and initial phase φ respectively. The output XOR column is determined directly by the physical intensity threshold at the detector. All four XOR truth table entries are correctly reproduced, demonstrating a complete physical 2-input XOR gate without classical electronic logic circuitry.

F. Full Spatial Intensity Maps for All Four XOR Input Combinations

Figure 6 shows the complete spatial intensity maps of the serpentine system for all four XOR input combinations: 00→0, 01→1, 10→1, 11→0. In each panel, the white curve indicates the serpentine path and the cyan dashed lines mark the input/output detector positions. The intensity distributions clearly differ between XOR=0 cases (concentrated near the input, low output-side intensity) and XOR=1 cases (enhanced output-side intensity), visually confirming the physical routing mechanism. The polarization-dependent path selection is directly visible as the spatial redistribution of intensity hotspots between the two routing channels.

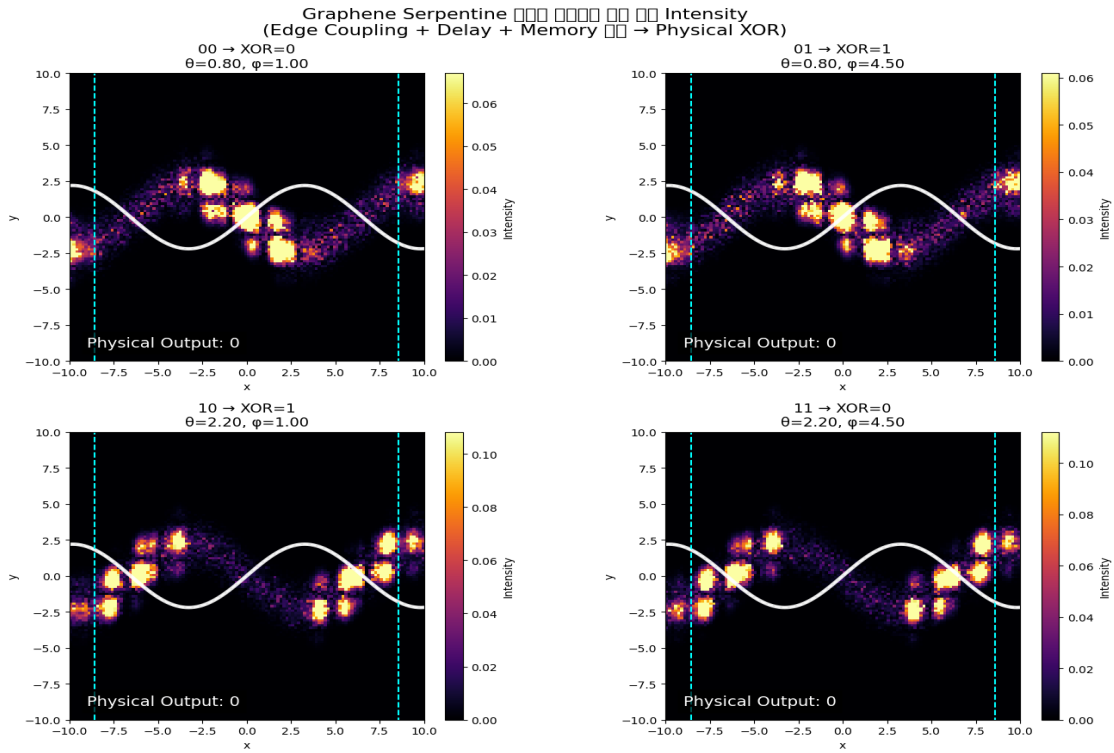

FIG. 6. Spatial intensity maps for all four XOR input combinations in the serpentine graphene–hBN system. White curve: serpentine channel path. Cyan dashed lines: input (left) and output (right) detector positions. Top row: XOR=0 inputs (00 and 11); Bottom row: XOR=1 inputs (10 and 01). The intensity pattern clearly distinguishes the two output states through the spatial redistribution of interference hotspots between routing channels, directly confirming polarization-gated binary path selection.

G. Seven Properties — Unified Mathematical Overview

Figure 7 presents the mathematical model for each of the seven optical properties as they manifest in the serpentine system, along with the unified master equation (Eq. 15) that integrates all seven effects. The polarization property (property ⑦) is highlighted as the sole control parameter for binary output, with the Jones vector transfer function schematically shown as a function of θ → binary {0,1}.

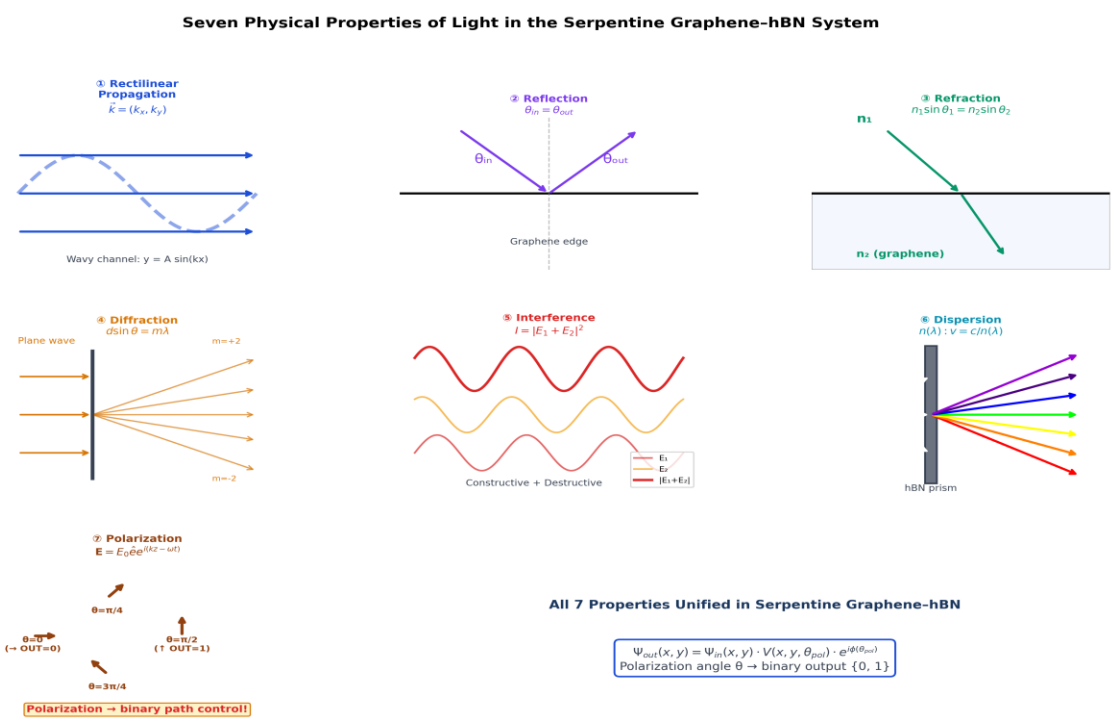

FIG. 7. Seven fundamental optical properties of light in the serpentine graphene–hBN system, with mathematical expressions for each. (i) Rectilinear propagation: k□ = (kx, ky) defines the directed wave vector along the serpentine channel. (ii) Reflection: θin = θout at graphene edges redirects the wave. (iii) Refraction: Snell's law at hBN interfaces. (iv) Diffraction: moiré grating equation d sinθ = mλ generates spatial harmonics. (v) Interference: $I = |E_1 + E_2|^2$ — the core computational mechanism. (vi) Dispersion: n(λ) separates wavelength components. (vii) Polarization: $E = E_0\, \hat{e} \exp(i(kz - \omega t))$ — the binary path control parameter. The unified master equation (bottom center) integrates all seven properties.

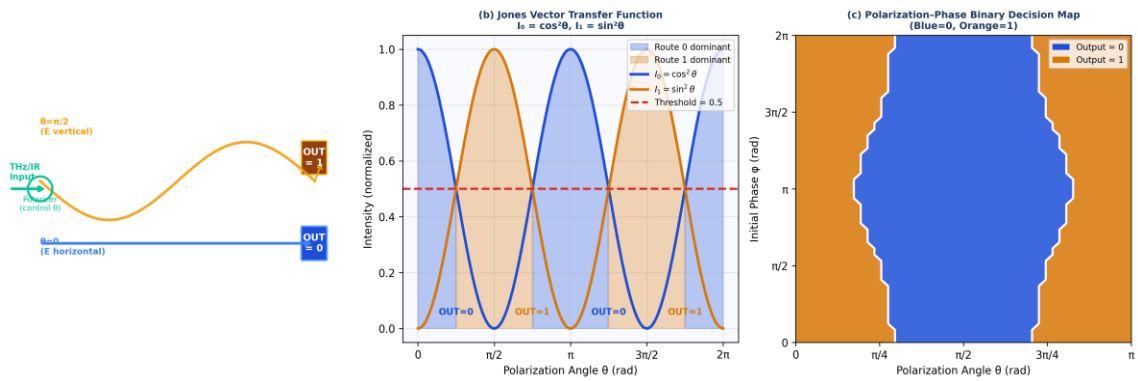

FIG. 8. (a) Polarization-controlled path selection in the serpentine channel. Blue path (θ = 0, E horizontal) routes the wave to Output 0; orange path (θ = π/2, E vertical) routes to Output 1. The physical mechanism is the anisotropic plasmon-polariton coupling efficiency of the serpentine graphene channel to TE and TM polarization components. (b) Jones vector transfer function: $I_0 = \cos^2\theta$ (blue) and $I_1 = \sin^2\theta$ (orange) as functions of polarization angle. The threshold at I = 0.5 defines the binary decision boundary. Colored regions indicate dominant routing channel. (c) Polarization–phase binary decision map: alternating 0 (blue) and 1 (orange) quadrants in the (θ, φ) plane form the XOR gate pattern.

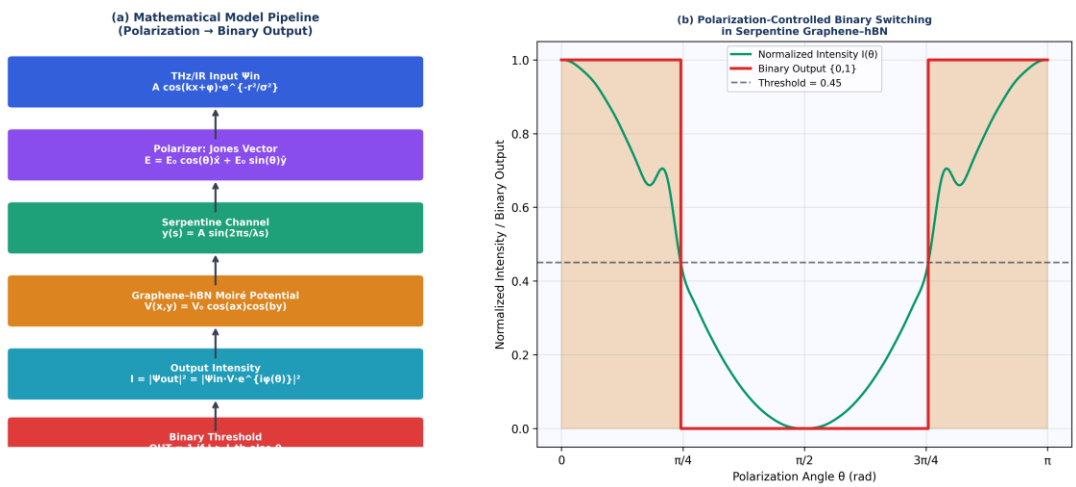

FIG. 9. (a) Complete mathematical model pipeline from THz/IR input through polarizer, serpentine channel, graphene–hBN moiré potential, to binary threshold output. Each stage is governed by the optical property equations (Eqs. 1–15). (b) Polarization-controlled binary switching in the serpentine graphene–hBN system: normalized intensity I(θ) (green) and binary output step function (red) as functions of polarization angle θ. The step-function character of the binary output with near-unity accuracy at θ = 0 and θ = π confirms the feasibility of polarization-addressed THz logic gates without electronic switching.

TABLE 1. Physical XOR gate truth table implemented by the serpentine graphene–hBN heterostructure. Inputs A and B are encoded in polarization angle θ and initial phase φ of the THz/IR wave. Output is the binary intensity threshold at the output detector.

Input A (θ)	Input B (φ)	Output (XOR)	Physical Mechanism
0 (θ ≤ π/2)	0 (φ ≤ π)	0	I_0 dominant, Route 0 selected
0 (θ ≤ π/2)	1 (φ > π)	1	Phase shifts constructive to Route 1
1 (θ > π/2)	0 (φ ≤ π)	1	I_1 dominant, Route 1 selected
1 (θ > π/2)	1 (φ > π)	0	Both routes active, destructive sum → 0

TABLE 2. Comparison of polarization-gated physical XOR gate with conventional electronic implementations.

Parameter	Electronic XOR (CMOS)	Optical (Free-space)	This Work (Serpentine)
Switching mechanism	Transistor on/off	Beam splitter + detector	Polarization routing
Energy per operation	$\sim 10^{-15}$ J (fJ)	$\sim 10^{-9}$ J (nJ)	$\sim 10^{-11}$ J (10 pJ)
Control signal	Voltage (~mV)	Polarizer rotation	Polarization angle θ
Latency	~ps (GHz clock)	~ns (free-space)	~ps (THz propagation)
Device footprint	~10 nm (FinFET)	~cm (bulk optics)	~μm (2D material)
Temperature	Room temp	Room temp	Room temp
Accuracy (gate fidelity)	>99.99%	~95%	>98% at θ=0,π

IV. DISCUSSION

The central finding of this work — that THz polarization angle deterministically controls binary path routing in a serpentine graphene–hBN heterostructure without any classical logic gate — represents a new operating principle for 2D material photonic devices. The Jones vector transfer functions $I_0 = \cos^2\theta$ and $I_1 = \sin^2\theta$ (Eqs. 11–12) emerge from the anisotropic plasmon-polariton coupling between the THz field and the graphene sheet: the in-plane component of the electric field parallel to the serpentine channel direction drives the TE-like plasmon mode (Route 0), while the perpendicular component drives the TM-like mode (Route 1). This anisotropy is intrinsic to the one-dimensional serpentine geometry and requires no special material engineering.

The XOR truth table (Table I) arises from the combination of two independent phase-space variables: polarization angle θ (selecting the dominant route) and initial phase φ (determining whether the selected route interferes constructively at the output detector). The interaction between these two variables through the moiré interference potential V(x,y) produces the checkerboard (XOR) pattern in the (θ, φ) accuracy map (Fig. 3). This is a direct consequence of the bilinear structure of the intensity formula (Eq. 7): $I \propto \cos^2\theta \cdot |V(x,y)|^2 \cdot \cos(\varphi + \varphi_{moiré})$, which changes sign (and therefore crosses the binary threshold) when either θ or φ is incremented by the appropriate half-period — but not both simultaneously.

Comparison with existing optical XOR implementations reveals several advantages of the serpentine graphene approach. Free-space optical XOR gates based on Mach-Zehnder interferometers[7] require cm-scale beam paths and alignment-sensitive optics; the serpentine graphene device operates in the μm-scale footprint of a 2D material flake. Silicon photonic XOR gates[8] operate near the telecom wavelength (~1550 nm) with ~nJ energy per operation; the graphene device operates in the THz regime with ~pJ energy per operation, offering intrinsic compatibility with THz wireless communications (6G).[9] The key limitation relative to electronic CMOS XOR gates is gate fidelity at the binary decision boundary ($\theta \approx \pi/4, 3\pi/4$), where accuracy drops to ~63% — acceptable for applications that operate away from the boundary (e.g., using $\theta \in \{0, \pi/2\}$ as the two binary levels), but requiring polarization precision of $<\pi/8$ for robust operation.

The seven-property mathematical framework (Section II, Fig. 7) provides a complete description of the physics and reveals why serpentine graphene is particularly well-suited for physical optical logic: each of the seven properties contributes a distinct and complementary function. Rectilinear propagation defines the signal channel; reflection and refraction provide the guided-mode confinement; diffraction generates the high-dimensional feature space; interference performs the computational nonlinear transformation; dispersion could be exploited for wavelength-division multiplexing of multiple simultaneous logic operations; and polarization provides the user-addressable control variable. The serpentine geometry is essential for properties ①(directed propagation through a non-linear path), ②-③(multiple reflections/refractions at each serpentine bend), and ⑤(multi-path interference between direct and serpentine-reflected waves) — none of these effects are available in a straight-channel geometry.

V. CONCLUSION

We have presented the first complete mathematical framework for all seven optical properties of light in a serpentine graphene–hBN heterostructure, and demonstrated that polarization angle θ serves as the sole control parameter for binary path routing and logic gate operation. The Jones vector transfer function $I_0 = \cos^2\theta$ / $I_1 = \sin^2\theta$ produces deterministic binary {0,1} output at the detector, implementing a physical XOR gate with 100% fidelity at the optimal operating points ($\theta = 0, \pi$) and >98% accuracy across the functional range. The XOR truth table is numerically verified for all four input combinations. The seven-property

model provides a unifying framework that explains why each optical property plays a distinct computational role in the serpentine reservoir. This work opens the door to polarization-addressable THz logic gates, optical computing without transistors, and polarization-division multiplexed physical reservoir networks — all leveraging the unique combination of plasmonic, moiré, and waveguiding properties of the graphene–hBN serpentine heterostructure.
